

Q1:

- a) Using a FAT file system:
  - $2000 * 4 = 8000$  bytes
- b) Using a UNIX-style file system:
  - 1<sup>st</sup> level index blocks =  $12 * 4 = 48$  bytes
  - Single indirect blocks =  $15 * 4 = 60$  bytes
  - 2<sup>nd</sup> indirect blocks =  $13 * 4 + 15 * 4 * 2 = 172$  bytes
  - 3<sup>rd</sup> indirect blocks =  $13 * 4 + 13 * 4 * 2 + 15 * 4 * 4 = 396$  bytes
  - Total =  $48 + 60 + 172 + 396 = 676$  bytes
- c) 1099
- d) 4<sup>th</sup> level down to the search

Q2:

- a) Using bitmap:
  - $1024 \text{ pages} * 1 \text{ bit} = 1024 \text{ bits} = 128 \text{ bytes}$
- b) Using a linked list:
  - $(1024 - 1) * 2 + 2 = 2048$  bytes (includes 1023 pointers from the page and one to head to the pages)
  -
- c) Linked list will be more memory efficient than bitmap when there are only few free space blocks.

Q3:

- a) FCFS scheduling:
  - $(97 - 84) + (155 - 84) + (155 - 103) + (103 - 96) + (197 - 96) = 244$
- b) SCAN scheduling:
  - $(103 - 97) + (155 - 103) + (197 - 155) + (199 - 197) + (199 - 96) + (96 - 84) = 217$
- c) LOOK scheduling:
  - $(103 - 97) + (155 - 103) + (197 - 155) + (197 - 96) + (96 - 84) = 213$

Q4:

The server first sends  $N$ , where  $N = p * q$ , to the user, the user stores  $N$ , and then sends  $N$  back to the server. Server verifies the  $N$  with  $p \& q$ . User randomly generates encrypted message  $K$  with pre-stored  $N$ , and send it to the server, server then uses  $K$  for AES. Then the SSH session is now encrypted with  $K$ .

A symmetric key  $K$  encrypts it, because only the server knows the private key, and can solve that to decrypt the symmetric key  $K$ . If the hack is fake, it will receive an encrypted message  $K$ , the server will decrypt that and send back to user some non-sense characters because the user can't decrypt the message
